Polarization over the Priority of Political Problems [*]

Benjamin E Lauderdale   *University College London*

Jack Blumenau   *University College London*

What drives ideological division about political problems? When prioritising which problems are most in need of redress, voters might disagree about the severity of individual outcomes that constitute such problems; the prevalence of those problems; or whether such problems are amenable to solution by government action. We field a large survey experiment in the UK and US and develop a new measurement approach which allows us to evaluate how ideological disagreements change when respondents consider the individual badness, social severity, and priority for government action of a set of 41 political problems. We find that large ideological divergences are observed in beliefs about social severity and priority for government action, not individual problem badness, and only in the US. An important implication of these results is that perceptions of problem prevalence are a key source of polarization over problem-prioritization in the US.

Introduction

Before governments can act to address problems, they must identify what those problems are. Governments cannot feasibly attend to all problems facing citizens, and consequently allocate attention and effort selectively. Just as disagreement often centres around the tradeoffs that arise when governments take one policy action over another, citizens might also disagree on the tradeoffs inherent in the decision to pursue solutions to one political problem over another. Where citizens disagree significantly over which political problems are most important to solve, any account of political polarization – that is, any account of ideological disagreement in the electorate – that focuses only on the issue *positions* that voters hold on how to solve such problems (e.g. Layman and Carsey, 2002; Hetherington, 2001; Abramowitz and Saunders, 2008; Fiorina and Abrams, 2008; Mason, 2013, 2015) is incomplete.

When conceptualized in terms of problem prioritization, political scientists have a surprisingly weak understanding of political disagreement. Despite a long history of research into public issue salience (Niemi and Bartels, 1985; Krosnick, 1990; Wlezien, 2005; Ansolabehere and Puy, 2018; Dennison, 2019), almost no work systematically assesses differences in problem prioritization across groups of voters. We argue that the lack of such comparisons partly reflects empirical and theoretical weaknesses in the study of problem prioritization. Empirically, standard measurement instruments for issue salience are subject to a number of well-known methodological limitations (Niemi and Bartels, 1985; Wlezien, 2005; Johns, 2010; Jennings and Wlezien, 2011; Bartle and Laycock, 2012) which make them poorly suited to capturing differences in issue importance across different groups of voters. Theoretically, the mechanisms through which voters come to see some political problems as more important or more in need of government attention remain under-theorised (Dennison, 2019, 442; Paul and Fitzgerald, 2021, 370), undermining our ability to understand the roots of any ideological disagreement that might exist.

In this paper, we make three contributions to the measurement and understanding of the public

prioritization of political problems. Our main theoretical contribution is a framework which emphasises that variation between voters about the priority ascribed to political problems might stem from three sources of disagreement. First, voters might hold different perceptions on the severity or "badness" of individual instances of a problem. Second, voters might have different beliefs about the prevalence of a problem. Third, voters might have different beliefs about the likely efficacy of government action to address a problem. While much existing work focuses on voters' differing beliefs about the problem badness, our framework highlights that all three sources of varying beliefs – about individual severity, societal prevalence, and government efficacy – might each play some role in observed levels of political polarization. While there are other ways we might delineate sources of disagreement over problem prioritisation, we think this is an intuitive decomposition of how voters come to view some problems as more or less politically important. We argue that separately and comparably measuring three sources of political disagreement allows for richer insight into the nature of problem prioritization and is necessary in order to understand where and how political polarization manifests.

Our second contribution is to develop a novel experimental measurement strategy for assessing the extent to which people disagree along ideological and political lines about these three features of political problems. To do so, we define a set of 41 political "problems", about which we query respondents using pairwise comparison experiments. We probe respondents' relative evaluations of these problems using different prompts to solicit information about the different types of disagreement that are the focus of our theoretical discussion. In one treatment condition, we ask respondents to make evaluations based on beliefs about the relative *badness* or *severity* of individual instances of the two problems: "Which of these do you think is worse?" A second condition asks respondents to evaluate the aggregate severity of that class of problem in a given country context, combining their beliefs about relative individual problem badness with their beliefs about the relative *prevalence* of the two problems: "Which of these do you think is a worse problem in the [US/UK]?" A final condition asks respondents to evaluate the relative priority for government action, combining beliefs about

aggregate severity with their beliefs about the likely *efficacy of government action* in addressing each problem: "Which of these problems should be the higher priority for the [US/UK] government to try to fix?" By comparing the distributions of responses to the paired-comparison tasks across the three prompts, we are therefore able to assess which of the three sources of variation in beliefs are most important in driving ideological conflict over problem prioritization.

Our experiment provides responses to paired comparisons including all 41 problems for each of the three prompts, which we analyse using hierarchical Bradley-Terry models (Loewen, Rubenson and Spirling, 2012; Blumenau and Lauderdale, 2022, 2023). The modelling framework we use provides several advantages, the most important of which is that it allows us to quantify the level of ideological disagreement over the rankings of the full set of problems, and allows us to directly compare the extent and patterns of disagreement between the individual, social, and government priority prompts. In addition, while the large number of problems we study means that we have relatively imprecise estimates of the level of ideological disagreement on any particular problem, the multilevel modelling approach we adopt nevertheless allows us to make statements about the average level of disagreement between left- and right-wing respondents across all of the problems in our experiment, and about the differences in average disagreement between our three prompts.

Our final contribution is empirical. We field our experiment to representative samples of citizens in the US and UK and demonstrate a number of important findings. We show that, in evaluating the severity of individual problems, those on the left and right, and in both the UK and US, make largely similar choices, such that the rankings of problem severity for those with opposing ideology are strikingly similar. We also show that, in both UK and US, voters provide different rankings of problems at the aggregate versus at the individual level in ways that clearly reflect the fact that some problems are more prevalent than others. In the UK, limited ideological disagreement carries forward from individual problem level to evaluations of problem severity at the social level and also to priority for government action. By contrast, in the US, evaluations of problem severity at the social level, and in terms of priority for government action, are much more polarized along ideological lines. These

evaluations are substantially more strongly predicted by self-reported ideology (and past vote) than is the case for individual problem instances. This is true to the point that the evaluations of liberals versus conservatives are only weakly positively correlated with one another across the 41 problems in our study. Ideological differences in US respondents' beliefs about the relative prevalence of social problems are likely to play an important role in explaining why we observe these different patterns in the two countries.

Our core findings are important for our understanding of the nature of US ideological polarization, which has been the object of extensive academic and non-academic attention in recent years. First, these findings reinforce our central argument that polarization over problem prioritization is a potentially important component of political disagreement. In particular, the ideological differences we uncover demonstrate that in addition to disagreeing over the correct government response to particular issues (e.g. Abramowitz and Saunders, 2008; Fiorina and Abrams, 2008), voters also disagree profoundly over which political problems are important to solve. As we argue below, understanding disagreement over "what matters" in politics is important because of the potential that such disagreement has for questions of political representation and cohesion. By providing new evidence on mass disagreement over problem priorities, we therefore enhance our understanding of the quality of political polarization in contemporary US politics.

Second, the pattern of results that we see forms strong evidence that variation in individual psychology plays only a partial role in explaining US polarization over the prioritization of different political problems, a finding that stands in tension to a growing literature on the moral foundations of political disagreement in the US (e.g. Koleva et al., 2012; Haidt, 2012; Kertzer et al., 2014). American liberals and conservatives do not disagree very much, or notably more than those on the UK left and right, regarding the individual instances of problems that are most narrowly and directly connected to individual moral psychology. The modest ideological differences in both countries tend to appear on the same issues and in the same directions. In contrast, when questions focus on social problems and priorities for government action, US liberals give responses that differ much more strongly from

5

those given by US conservatives. The polarization we document in in the US, then, does not appear to stem from differences between liberal and conservative judgments of the badness of specific events, but rather from differences in the ways in which voters perceive the frequency of those events.

Polarization over Problem Prioritization

An extensive literature in political science documents the levels and trends of attitudinal conflict in the US electorate (Hetherington, 2001; Layman and Carsey, 2002; Abramowitz and Saunders, 2008; Fiorina and Abrams, 2008; Mason, 2013, 2015).[1] In particular, the extent of issue-based polarization – defined as the degree to which citizens take ideologically extreme positions on different policy issues – is the subject of ongoing debate, with some arguing that there are large and growing attitudinal divides among the US public (e.g. Abramowitz and Saunders, 2008) while others suggest that mass policy attitudes remain relatively moderate (e.g. Fiorina and Abrams, 2008). However, while ideological disagreement over policy is clearly one important quantity of interest in the study of polarization, political contestation does not *only* reside in the issue positions that voters adopt. An additionally important, and in some sense logically prior, question is whether and how far voters agree about the relative priority of the different problems that governments might seek to address through policy. Despite extensive debate over the conceptual meaning of polarization,[2] researchers have largely ignored the possibility that voters might have systematically divergent attitudes about the priority given to addressing different political problems.[3]

Public (dis)agreement over "what matters" in politics is important to understand for a number of reasons. First, high-quality political representation requires some level of correspondence between the attention paid by political actors to different issues and the priority ascribed to those issues by the public. To the extent that the public disagrees strongly about the ordering of public priorities, the

---

[1] Issue-based disagreements are also seen as an important feature of politics in many countries (e.g. Kleiner, 2020; Bischof and Wagner, 2019; Hübscher, Sattler and Wagner, 2023).

[2] See Hetherington (2009) for a review of this literature.

[3] Where issue salience is considered, it is mostly as a weight that might affect the relevance of position-based polarization (Hetherington, 2009, 434-6).

agenda pursued by the government may correspond only to the priorities of some of the electorate. Second, ideological conflict over what constitutes an important problem is arguably a more serious form of polarization than ideological disagreement over the appropriate policy solution to a problem that everyone sees as important. As Paul and Fitzgerald (2021, 391) suggest, a cohesive society "is one in which different groups may disagree on a particular issue, but they are in agreement about what issues are the most and least important in society." On this view, whether citizens share similar perspectives on the relative ordering of different political problems is a critical aspect of social and political cohesion.

How much do we know about public disagreement over problem importance? While researchers studying public issue salience (Krosnick, 1990; Dennison, 2019) have described variation in the aggregate importance of issues over time (e.g. Wlezien, 2005) or used individual-level measures of issue importance to inform models of voting (e.g. Niemi and Bartels, 1985; Krosnick, 1990; Ansolabehere and Puy, 2018), few studies evaluate the degree to which different groups of voters disagree about the relative priority of different political problems.[4] We argue that the lack of such comparisons are related to empirical and theoretical weaknesses in the study of problem prioritization.

Empirically, measures of issue salience overwhelmingly rely on survey questions that ask respondents to report the most important "problem" (MIP) or "issue" (MII) facing their country, but these instruments are subject to a number of well-known methodological limitations (Niemi and Bartels, 1985; Wlezien, 2005; Johns, 2010; Jennings and Wlezien, 2011; Bartle and Laycock, 2012). First, by focusing on the *most* important problem, these prompts provide little information about the prioritization of problems beyond what is currently getting the most political attention. Second, these questions often yield broad consensus answers, such as "the economy". However, when voters say "the economy", some might be referring to unemployment, others to inflation, and others still to wages or other concrete issues. The lack of specificity engendered by the open-ended response format therefore makes comparisons of salience across groups hard. Third, some scholars have argued that the

---

[4]Though see Paul and Fitzgerald (2021) and Neundorf and Adams (2018, 393,402).

open-ended nature of the MIP/MII prompt places unreasonable cognitive demands on voters (Bartle and Laycock, 2012), and that, as a consequence, voters' responses to the MIP/MII question may be more likely to reflect "what they believe the rest of the electorate believe to be important, making MII responses useful only at the aggregate level" (Dennison, 2019, 439-40). If MIP/MII questions reveal the importance of problems to an *average* voter then they are unlikely to be informative about the degree of disagreement *between* voters of different ideological types.

Beyond proposals for some (relatively minor) alterations to the wording of the MIP/MII question (e.g. Wlezien, 2005, 575; Johns, 2010, 156), there has been remarkably little work which aims to develop new survey instruments better suited to capturing differences in prioritization across groups. One alternative to the MIP/MII question is single rating of different problems (e.g. Arceneaux and Kolodny, 2009), but this approach is also limited by the challenges of comparability of single ratings, the ambiguous scales on which such questions are measured (e.g. "very important", "somewhat important", etc), as well as the cognitive demands imposed on respondents by providing ratings across a large number of problems. An important obstacle, therefore, to developing understanding of disagreements about problem salience is the lack of appropriate tools to measure such attitudes.

Theoretically, understanding *how* voters form attitudes about the relative priority of different problems is a pre-requisite for being able to explain why disagreements between voters about such priorities might arise. However, while existing work assumes that perceptions of problem importance stem from voters' values, self-interest, and group-identification (e.g. Krosnick, 1990), this work is imprecise about how these mechanisms might lead to polarization in prioritization and is silent on other sources of influence that might affect voters' perceptions of problem importance. As a consequence, the mechanisms that determine attitudes in this domain remain "under-theorised" (Dennison, 2019, 442) and "underdeveloped" (Paul and Fitzgerald, 2021, 375). Thinking carefully about the sources of variation in perceptions of problem importance is an important step if we are to understand, and not merely measure, disagreement in such perceptions between voters.

Why might voters on the left and right come to disagree over the importance of political prob-

lems? A prominent explanation for issue-based polarization comes from the literature on social psychology, which views policy preferences as – at least in part – causally downstream of voters' psychology (e.g Jost et al., 2003; Lakoff, 2010; Haidt, 2012). Moral Foundations Theory (MFT), for instance, suggests that while the liberals tend to assign more weight to principles of care and fairness, conservatives put greater stock in principles of loyalty, authority and sanctity (Graham, Haidt and Nosek, 2009; Graham et al., 2011; Haidt, 2012). These moral-psychological differences are thought to explain issue-based polarization (Koleva et al., 2012; Kertzer et al., 2014), political extremism and hostility (Ryan, 2014, 2017), and affective polarization (Garrett and Bankert, 2020; Simonsen and Bonikowski, 2022). Could voters' moral predispositions also affect the priorities they assign to different political problems? The implicit causal model in these accounts is that different psychological predispositions or intuitions will lead citizens to differentially perceive the moral disutility of certain actions, events, or conditions. As a consequence, if voters of different ideological types do possess fundamentally contrasting moral "intuitions", then this might translate into different perceptions of the priority of different political problems, as different problems will relate more or less to particular moral concerns.

However there are other sources of disagreement that might also plausibly drive ideological contestation. We argue disagreement over problem prioritisation might arise from three types of variation in beliefs. First, consistent with the perspectives above, voters might differentially perceive the *severity or "badness"* of individual instances of a problem. Second, citizens might disagree about the relative *prevalence* of the problem. Third, citizens might additionally disagree about the extent to which that problem is *amenable to government action*. While the existing literature stresses the importance of the citizens' perceptions of the severity of individual problems, ideological disagreement about what government ought to prioritise may also reflect disagreements in citizens' beliefs about both problem prevalence and the efficacy of government action.

9

From Individual Events to Social Problems to Government Priorities

In this section, we provide a simple formalization of these sources of disagreement to explicate the types of logical relationships that might exist between them. The quantities we are interested in are beliefs of citizens i. We are interested in beliefs about the individual badness or disutility of different types of problems j (e.g. an individual murder, inflation felt by an individual, etc) that occur in multiple instances. We denote the *average individual* disutility of all instances of the type of problem as D_{ij}. We are further interested in beliefs about the *social* disutility S_{ij} of those problems (e.g. murders in society, inflation felt across the entire society, etc) when aggregated across all such instances k of that type j. Finally, we are interested in beliefs about the payoff (utility) to *government action G_{ij}* for each of these problem types j. We do not expect the rankings that citizens have of D_{ij}, S_{ij} or G_{ij} to be the same across a given set of problem types j. In order to illustrate this point, we start by relating beliefs regarding individual (D_{ij}) and social (S_{ij}) disutility, and we then relate social disutiilty (S_{ij}) and payoffs to government action (G_{ij}).

While not the only way to relate the badness of aggregate social problems (S_{ij}) to the badness of the average individual instances of those problems (D_{ij}), a basic additive utilitarian calculus relating the two is a natural place to start considering the origins of potential disagreements:

$$S_{ij} \quad = \quad N_{ij} \cdot D_{ij} \tag{1}$$

That is, one way for an individual i to think about how bad a problem is for society (S_{ij}) is as the sum of the badness of each instance in which it occurs, or equivalently, the product of that individual's belief about its prevalence in society (N_{ij}) and its average severity (D_{ij}) in the individual instances where it occurs. Thus a problem which is very severe in each individual instance, but relatively rare, might be viewed to be a lesser problem at the societal level than another problem which, while less severe, is far more prevalent. An individual i might assess that the average badness of an instance of someone being murdered is worse than an instance of someone experiencing inflation ($D_{i,murder} > D_{i,inflation}$)

but also that murder is a lesser aggregate problem in society than inflation ($S_{i,murder} < S_{i,inflation}$) because inflation affects everyone while very few people are murdered.

We can make a similar case for a divergence between S_{ij} and G_{ij}. Assuming that governments are going to be better able to address some societal problems than others, we can define a coefficient or elasticity of government action (E_{ij}) for a given problem type that describes the marginal efficacy of government action in reducing the aggregate social problem (S_{ij}) per unit of government effort/resources.[5] We can then express payoffs to government action on a given problem (G_{ij}) as a function of the aggregate social badness of a problem (S_{ij}) and the efficacy of government action (E_{ij}):

$$G_{ij} = E_{ij} \cdot S_{ij} \tag{2}$$

Thus, just as an individual might rank the individual severity of a problem in a given instance differently from the aggregate social severity of that problem type because they believe the problems occur at different rates (N_{ij}), they might rank the aggregate social severity differently from the priority of government action on that problem type because they believe the problems are differently amenable to government remediation (E_{ij}).

In the data analysis that follows, we work with the log-scale equivalents of these quantities $d_{ij} = \log(D_{ij})$, $s_{ij} = \log(S_{ij})$, $g_{ij} = \log(G_{ij})$, $n_{ij} = \log(N_{ij})$, and , $e_{ij} = \log(E_{ij})$, which have additive relationships:

$$s_{ij} = n_{ij} + d_{ij} \tag{3}$$

$$g_{ij} = e_{ij} + s_{ij} \tag{4}$$

Working on an additive scale makes differences the natural measure of disagreements, and also links the quantities at the individual level described in the theoretical model above to population and sub-population averages that we can feasibly estimate over sets of individuals i.

---

[5]One could think here of government effort here in a generalised capacity sense or in a narrower financial cost sense.

These theoretical connections have implications for what we learn from different patterns of ideological disagreement about these quantities. Imagine that we define two population subgroups, corresponding to the ideological left (L) and right (R), and define corresponding averages d_{jL}, d_{jR}, s_{jL}, etc. If we observe ideological disagreement about individual problem severity, i.e. a non-zero value of $d_{jR} - d_{jL}$, we would expect it to carry through into ideological disagreement in social problem severity ($s_{jR} - s_{jL}$) because $s_{jL} = n_{jL} + d_{jL}$ and $s_{jR} = n_{jR} + d_{jR}$, *unless* there is a countervailing ideological disagreement about problem frequency ($n_{jR} - n_{jL}$). We would further expect ideological disagreements in social problem severity to carry through to become ideological disagreements in government action priority, unless there is a countervailing ideological disagreement about government efficacy ($e_{jR} - e_{jL}$).

Those who argue that differences in psychology underpin political disagreements focus, either implicitly or explicitly, on different rankings of d_{ij} (e.g Jost et al., 2003; Haidt, 2012). These accounts imply that because liberals and conservatives evaluate the relative severity of individual *instances* of problems differently, this will translate into different prioritisations of those problems in the political arena. But this formalisation clarifies that disagreement over the relative badness of individual instances of different problems is only one of the potential sources of ideological disagreement about social problems and priority for government action. For instance, equation 3 reveals that ideological disagreement about problem frequency ($n_{jR} - n_{jL}$) could lead disagreements about social problem severity ($s_{jR} - s_{jL}$) to be either amplified or attenuated versus those present in individual problem severity ($d_{jR} - d_{jL}$), depending on whether those disagreements point in the same direction or not on a given problem j. The same logic again applies between social problem severity and priority for government action.

We might also ask whether these ideological disagreements are *generally* positively or negatively correlated across problems. Positive correlations between $d_{jR} - d_{jL}$ and $n_{jR} - n_{jL}$ across a set of problems j would mean that individuals on the right/left tend to believe that the problems which they think are *worse* at the individual instance level are also more *prevalent* in society (relative to what

those on the other side think). Another possibility is that there is little/no ideological disagreement about individual problem severity (d_{jR} - d_{jL}) but disagreements about social problem severity (s_{jR} - s_{jL}) and/or priority for government (g_{jR} - g_{jL}) arise by virtue of ideological disagreement about problem frequency (n_{jR} - n_{jL}) or amenability to government remediation (e_{jR} - e_{jL}). The less that disagreements about s_j and g_j arise from disagreement about individual problem severity, and the more they arise from disagreements about problem frequency or amenability to government remediation, the more we have reason to doubt that moral or values-based divisions fully account for ideological conflict over political problems. Disagreements about problem frequency and amenability to government remediation are disagreements about the factual state of society and about feasible public policy, rather than disagreements about what is right and wrong.

While individuals' beliefs might interact in more complicated ways, these simple theoretical relationships are nevertheless useful for identifying beliefs about relative prevalence and government efficacy as important potential locations for understanding how disagreements over problem prioritisation between individuals might form.

Experimental Design

In this section we describe the design of a survey experiment fielded to YouGov samples of 1763 UK and 2304 US respondents from 6-11 January 2023. Our experiment asked respondents to make choices between pairs of political problems, where the types of decisions they were asked to make varied between question prompts in ways that correspond to our theoretical discussion above. That is, respondents were asked to compare individual problems, social problems, and government priorities with respect to a specified list of problem types.

Our design has a number of virtues relative to open-text MIP-style questions and long lists of closed response options. First, by asking respondents to make comparisons between pairs of problems, we directly solicit judgments about the *relative* priority/importance they would ascribe to these problems. Second, the question formats we use elicit *personal* judgments of importance, rather than

impressions of the importance of issues to other people, and do so along several theoretically relevant dimensions of disagreement. Finally, the task we present is minimally demanding from a cognitive perspective.

Defining the Problem Set

For the purposes of this study, we define a "problem" as a type of event that is understood by at least some people as being associated with a bad outcome. It is difficult to identify a "true" population of problems, and so to achieve reasonable coverage of the problems that tend to be relevant to politics, we reviewed newspapers of varying types and political leanings in the US and UK to identify the kinds of problems that receive media attention either as individual events (e.g. someone was murdered in described circumstances) or as a social problem (e.g. the murder rate has changed versus last year). Included in our set are several problems which have been extensively studied in the political science literature, such as various types of crime, inflation, unemployment, and shark attacks.

For each of the 41 problems we include in the experiment, we specify the problem both in the form of an individual instance and also as a social or aggregate problem type that has many instances. For example, one problem in an "individual" form is "A young person is killed by a gang", which is adapted to "Young people being killed by gangs" in its "social" form. All the problems were written in forms that could be presented to US and UK audiences with only minimal need for localisation (e.g. "trash" versus "rubbish"). Appendix table A1 contains the full texts of all 41 treatments.

Problem Comparison Questions

Our main experiment consists of pairwise comparisons of problems, under three different prompts which correspond to the three mechanisms discussed above:

1. *Individual Prompt*: "Which of these do you think is worse?"
2. *Social Prompt*: "Which of these do you think is a worse problem in the [US/UK]?"

YouGov

Which of these do you think is worse?

> A person being addicted to drugs or alcohol.

> High interest rates make it impossible for someone to buy a home.

> They are about the same

> \>

Figure 1: Example of experimental presentation, for the individual prompt.

3. *Government Prompt*: "Which of these problems should be the higher priority for the [US/UK] government to try to fix?"

These prompts were designed with the aim of eliciting responses that reflected respondents' evaluations regarding the relative values of (1) d_{ij}, (2) s_{ij}, and (3) g_{ij} respectively for the two problems j presented. Respondents were randomly allocated, with equal probability, to the individual prompt, the social prompt, or the government prompt. Each respondent then provided answers to that prompt for six randomly selected pairs of problems. For each of these, the respondent had a choice between two problems and a neutral option ("They are about the same"). An example of the individual prompt, for one pair of problems, is provided in figure 1.

This design yields only a very small number of responses per problem pair. We have an average of 4 responses per pair, per prompt in the UK sample and 6 in the US sample. The strength of pairwise comparison designs comes from the larger number of appearances per problem. Each problem appears an average of 172 times per prompt in the UK sample and 225 times per prompt in the US sample, against a range of different "opposing" problems. This gives information about how respon-

dents rate problems against a given prompt, relative to all others, which can be characterised using Bradley-Terry models as described below.

We observe slightly higher rates of neutral responses in the social prompt (UK: 26%, US: 28%) and government action prompts (UK: 24%, US: 29%) than in the individual prompt (UK: 23%, US: 25%). There was no evidence of order effects in the sense of individuals selecting the problems shown on the left versus the one shown on the right.

Additional prompts to explore mechanisms

Our pairwise comparison experiment yields data with respect to individual problem severity (d), social problem severity (s), and government action priority (g), as defined earlier, but not perceptions of problem prevalence (n) and efficacy of government action (e). We therefore included survey questions *after* the pairwise comparisons that relate to these quantities.

To assess beliefs about the prevalence of each problem type, we ask half of the respondents who answered the individual prompt and all respondents who answered the government prompt to rate how frequently people experience a random three of the problems that *did not* appear in that respondent's pairwise comparisons. The prompt we use is, "For each of the problems listed below, how often do you think these occur in the [US/UK]?", with an 11 point scale from "Extremely rarely" (0) to "Extremely frequently" (10).

To assess beliefs about government efficacy, we ask the other half of the respondents who answered the individual prompt and all respondents who answered the social prompt to rate how effective government is in addressing a random three of the problems that *did not* appear in their pairwise comparisons. The prompt we use is, "For each of the problems listed below, how easy would it be for government action to reduce the problem in the [US/UK]?" with an 11 point scale from "Completely impossible" (0) to "Extremely easy" (10).

While these single rating questions have important limitations, which is why we do not use them for measuring d, s and g, they give us a way to assess whether ideological group level disagreements

about prevalence (n_{ij}) and efficacy (e_{ij}) are associated with corresponding disagreements in responses to the pairwise comparison questions which yield measurements of *d*, *s* and *g*. We chose to measure disagreement on these quantities using the scale-based questions because using five pairwise comparison experiments (rather than three) with disjoint respondent sets would have increased the uncertainty surrounding our estimates of each problem to the degree that would have made it difficult for us to make inferences about the relative ideological polarization that manifests on each prompt. We emphasize that we ask these questions *after* the pairwise comparisons rather than before, and of respondents who were not asked the most obviously relevant pairwise comparison prompt. This avoids priming respondents to focus on prevalence or efficacy in the pairwise comparisons, and it also avoids encouraging respondents to justify their specific pairwise response answers when answering the prevalence or efficacy ratings.

Ideological Self-Placement

We also ask questions to measure respondents' pre-treatment ideological self-placement. For the UK sample we asked "In politics people sometimes talk of left and right. Where would you place yourself on the following scale?", with 7 response options ranging from "Strongly left" to "Strongly right". For the US sample, we asked: "In politics people sometimes talk of liberals and conservatives. Where would you place yourself on the following scale?" with 7 response options from "Strongly liberal" to "Strongly conservative". For our main analyses we group all liberal/left of centre and all conservative/right of centre responses. In the UK, our population-weighted sample splits 32% Left, 46% Moderate, 22% Right. In the US, our population-weighted sample splits 31% Liberal, 34% Moderate, 35% Conservative.

We conduct some analyses using past vote choice from the 2019 UK and 2020 US general elections. These were not asked during the survey, but were already held by YouGov for their panellists. For these, under the groupings we use, our UK sample splits 31% Labour, 27% Other/None, 42% Conservative. Our US sample splits 31% Biden, 41% Other/None, 28% Trump.

Modelling Problem Priorities

Our pairwise comparison questions result in an ordered response variable for each response i with three categories:

$$
Y_i \in \begin{cases} 1 = \text{Problem 2 is worse / higher priority} \\ 2 = \text{About the same} \\ 3 = \text{Problem 1 is worse / higher priority} \end{cases} \tag{5}
$$

To model this outcome, we adopt an ordinal probit variation on the Bradley-Terry model for paired comparisons (Bradley and Terry, 1952; Rao and Kupper, 1967) where we model a latent response comparing problem j and problem j' according to a cutpoint model:

$$
Y_i^* = \alpha_{j(i)} - \alpha_{j'(i)} + \epsilon_i \tag{6}
$$

$$
Y_i = \begin{cases} 1 \text{ if } Y_i^* \le \theta_1 \\ 2 \text{ if } Y_i^* > \theta_1 \ \& \ Y_i^* \le \theta_2 \\ 3 \text{ if } Y_i^* > \theta_2 \end{cases} \tag{7}
$$

When we fit this model to the data from the individual prompt, $\alpha_j = d_j$; from the social prompt, $\alpha_j = s_j$; and from the government prompt, $\alpha_j = g_j$. Our core research questions involve making comparisons of the ranking of the 41 problems j we include in the experiment between prompts, countries, and ideological subgroups of respondents. To facilitate these comparisons, we adopt a hierarchical modelling framework in which we directly estimate the correlation of the Bradley-Terry "severity" parameters α between conditions and sub-groups by making the correlation itself a model parameter in a "correlated severity" model (Blumenau and Lauderdale, 2023). This model starts with the first-stage model described in equation 6 in order to determine whether different groups of people rate problems as worse than others in different ways on average. We then hierarchically model the $\alpha_{j,p}$ parameters by assuming that they are drawn from a multivariate normal distribution with mean

zero and covariance matrix Σ:

$$\alpha_{j,p} \sim MVN(0, \Sigma) \tag{8}$$

Here, Σ has diagonal elements σ_p^2 and off-diagonal elements $\sigma_p \sigma_{p'} \rho_{p,p'}$. The correlations ρ are our primary interest, as these tell us whether the relative severity/priority of the problems, across our entire experiment, tend to be similar for a pair of prompts or groups p and p' ($\rho_{p,p'} \gg 0$), whether the problems that are considered to be bad by one group are uncorrelated with those that are considered bad by the other ($\rho_{p,p'} \approx 0$), or whether the groups systematically disagree about which problems are worse ($\rho_{p,p'} < 0$). We estimate this model for variously defined groups p in the analyses below.

In the appendix, we provide further mathematical detail, including a discussion of the theoretical link between individual responses and group average preferences, and a version of the model where we allow the problem severity parameters to vary as a linear function of multiple predictors.

National Results

For our initial presentation, in figures 2, 3, and 4, we show the estimates of the $\alpha_{j,p}$ parameters from the first-stage ordinal logistic Bradley-Terry model estimated separately for each prompt in each country. The points are sorted by the average of the US and UK estimates for a given problem on the prompt.

In the aggregate, US and UK citizens make similar evaluations of the relative severity of individual problems, and only slightly less similar evaluations on the relative severity of social problems and of priority for government action. The correlation between the UK and US estimates for the individual problem prompt is 0.95, while the corresponding cross-country correlations for the social problem prompt and government action prompts are 0.86 and 0.86, respectively.

There are some differences with respect to specific problems on specific prompts, most of which reflect understandable differences between UK and US politics. On the individual problem prompt (figure 2), US respondents rate "A teenager takes medication which alters their hormones to match their gender identity" and "A woman has an abortion" as worse on average relative to the other problems than do UK respondents, likely reflecting the larger number of social conservatives who view

Figure 2: Bradley-Terry Estimates for severity of individual problems, in the UK (blue) and US (red).

Figure 3: Bradley-Terry Estimates for severity of social problems, in the UK (blue) and US (red).

Figure 4: Bradley-Terry Estimates for priority for government action, in the UK (blue) and US (red).

these as relatively serious problems in the US versus UK. US respondents also rate "The police stop and search a person without reasonable suspicion of criminal activity" as worse than UK respondents do, possibly reflecting different formal rights in the two countries.

On the social problem prompt (figure 3), the notably different items are "Mass shootings with many deaths", "People being bankrupted by medical expenses" and "Women having abortions", all three of which are viewed as substantially worse problems in the US than the UK. The former two reflect the reality that these occur far more frequently in the US than the UK. The disagreement on the abortion issue is likely to reflect both the differences about the individual morality of having an abortion as well as how this is translated into perceptions of a social problem, which we discuss further below.

On the government action prompt (figure 4), we see UK respondents are inclined to prioritize government action on "Rising prices reducing peoples' standards of living" and "Rising energy prices forcing businesses to close" higher than US respondents. Inflation, and particularly energy prices, were high profile in both countries in early 2023, however the UK government's intervention in energy markets in late 2022 was far larger in scale than any in the US.

Overall, the results suggest that respondents responded to the different prompts in ways that make sense given the questions that were being asked. In both the US and UK, people make distinctions between the relative severity of individual instances of problems and their aggregate consequence. The correlation between the individual prompt estimates and the social problem prompt estimates was 0.65 in the UK and 0.74 in the US. By contrast, in both the US and UK, people make less distinction between the relative severity of social problems and which problems government should prioritize addressing. The correlation between the social problem prompt estimates and the government action prompt estimates was 0.94 in the UK and 0.90 in the US.[6]

Our theoretical discussion suggests that differences between individual and social prompts will appear when there are differences in beliefs about the prevalence of different kinds of bad events.

---

[6]Figures A1 and A2 show the differences between the individual and social prompts and the social and government prompts, for each problem.
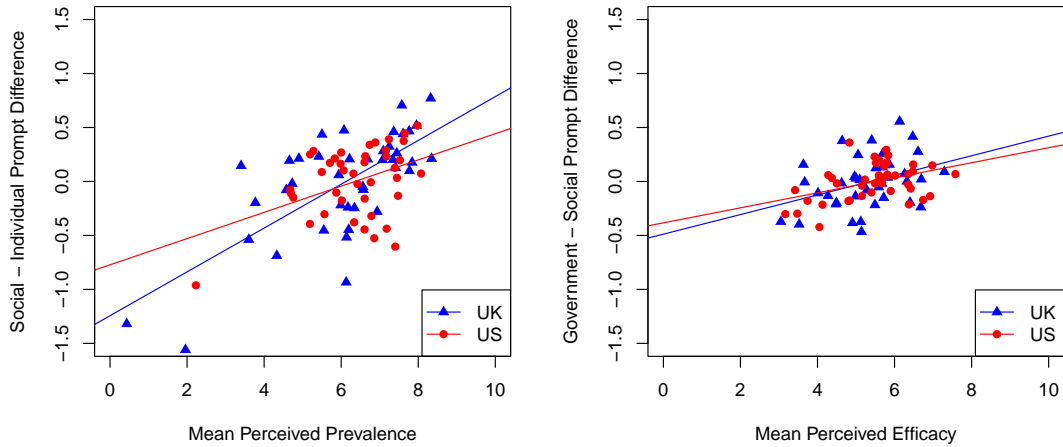

Figure 5: Differences in Bradley-Terry Estimates between social and individual prompts (left) and government and social prompts (right), in the UK (blue) and US (red), as a function of average perceived problem prevalence (left) and average perceived government efficacy (right). All four linear regression lines have statistically significant slopes.

Similarly, differences in perceptions of social problem severity and priority for government action will arise when people hold different perceptions of the which social problems can be addressed by government action. Figure 5 presents some initial evidence that supports these theoretical intuitions. The left panel shows a positive significant relationship, in both the UK ($p < 0.001$) and US data ($p = 0.006$), between the mean perceived prevalence of problems (measured using the 11-point scale question), and the difference in the estimated severity of problems in the social and individual prompts. This implies that when, on average, respondents view a problem as higher prevalence (n_{ij}), average perceptions of social problem severity (s_{ij}) increase relative to perceptions of individual problem severity (d_{ij}). The right panel shows that there is also a positive significant relationship, in both the UK ($p = 0.019$) and US ($p = 0.006$), between the mean perceived efficacy of government action for addressing each problem, and the difference between the estimate for that problem in the government action prompt and in the social problem prompt. Again, these patterns are consistent with our theoretical argument: when comparing problems with equal perceived social severity (s_{ij}), respondents will give greater priority (g_{ij}) to those problems where they believe the government is more likely to be efficacious (e_{ij}).

Results by Ideology

We now turn to our primary research question and ask to what extent, and on which prompts, are there differences between left/liberal and right/conservative voters?

Ideological Gaps by Problem

Figure 6 shows the problem estimates for those who self-report as right/conservative minus the estimates for those who self-report as left/liberal for the individual severity prompt ($d_{jR} - d_{jL}$). We present equivalent plots for the social severity and government priority prompts in appendix figures A3 and A4. These plots are again sorted on the average of the UK and US ideological differences, and clearly indicate that in general there is a tendency to see ideological differences in the same direction with respect to specific problems in both countries.

In the individual prompt (figure 6), for example, "A teenager takes medication which alters their hormones to match their gender identity" and "An immigrant enters this country illegally" are among the items viewed as much more serious problems by people on the right in both countries, while problems related to child hunger, medical bankruptcy, tax evasion by the wealthy and police stops are all viewed as more serious problems by people on the left in both countries. There are some items that are only politically aligned in one country and not the other (e.g. abortion and vaccination in the US and not the UK, employees not working hard and business fraud in the UK). There is just a single item which has substantial ideological alignments in both countries, but in the opposite directions: US conservatives and the UK left are more concerned about teenagers watching pornography than their respective domestic counterparts. There is a similar tendency for the left/right and conservative/liberal differences to covary across the two countries in the social problem and government action prompts also, with some variation in the details (see appendix figures A3, and A4).

In Figure 7, we show that there is – as expected under the theoretical model described above – also strong association between the ideological gaps across prompts. If there is an ideological gap in
Figure 6: Difference in Bradley-Terry Estimates between right/conservatives and left/liberals, for individual prompt, in the UK (blue) and US (red).

perceptions of individual severity (d_{ij}) then we would, at least on average, expect that to carry over to perceptions of social severity (s_{ij}), which is what we see in the left panel of the figure. Similarly, ideological gaps in perceptions of social severity (s_{ij}) will generally correlate with ideological differences in priorities for government action (g_{ij}), which is what we see in the right-hand panel. However, we note that in the left panel of Figure 7 there is a tendency for the magnitude of ideological gaps to be *amplified* between the individual prompt and the social prompt in the US. That is, where US liberals and conservatives disagree about how bad a given problem is in an individual instance, they tend to disagree *even more* about how bad that problem is for society. The slope[7] describing this relationship is 1.63. With only 41 problems, this slope is an imprecise estimate of the slope across a broader population of problems; however it is significantly different from 1 when we resample problem-level estimates using a non-parametric bootstrap (95% interval: 1.29 - 2.48). For all the other comparisons–UK individual to social (1.00), UK social to government (0.87), US social to government (0.89)–there is an approximately one-to-one association between the ideological differences by problem between prompts.

Divergent Views of Severity and Priority

This discrepancy leads us to the most important pattern of difference that we find between US and UK respondents. Figure 8 shows that the above patterns of agreement and disagreement have markedly different implications for the extent to which left/liberals and right/conservatives agree on the relative rankings across the three different prompts. In the UK, the correlation between how the left and right view the relative severity of problems and their priority for government action is high and mostly stable across prompts. In contrast, while the correlation between liberals and conservatives in the US on prompt 1 is nearly as high 0.75 (0.09) as for the UK 0.81 (0.07), the correlations between the views of liberals and conservatives in the US are far lower with respect to the social problem

---

[7]We use perpendicular regression lines—principle components analysis on two variables—because these treat x and y variables symmetrically, which is appropriate given that both are measured with error, neither has any claim to be causally or predictively prior to the other, and we are simply interested in providing a linear description of their association.
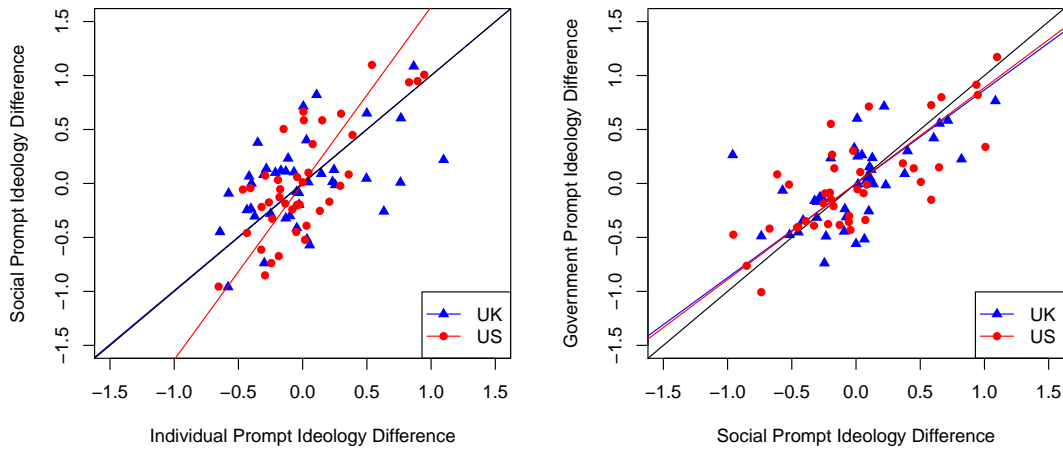

Figure 7: Differences in Bradley-Terry Estimates for each problem between right/conservatives and left/liberals, in the UK (blue) and US (red). Left panel shows comparison of social prompt (y-axis) versus individual prompt (x-axis), right panel shows comparison of government prompt (y-axis) versus social prompt (x-axis). Black line is x = y; blue and red lines for UK and US are via least perpendicular distance regression.

prompt 0.36 (0.16) and government action prompts 0.38 (0.16). This is true both by comparison to the UK equivalents, 0.71 (0.10) and 0.82 (0.07), and also to the US respondents on the individual problem prompt.

In both countries, we find the same pattern of results by past vote as by self-reported ideology (see appendix figure A5) and so we cannot simply ascribe the difference between the two countries to the different wording and meaning of the labels in the ideology question. US liberals and conservatives have starkly different political priority lists in a way that the UK left and right do not. If we look at some of the extreme 'off-diagonal' cases in the government priority prompt, we see that whereas "Immigrants entering this country illegally" ranks 1 of 41 in priority for government action among US conservatives, it ranks 35 of 41 among US liberals. On the other hand, whereas "Young people being unable to pay off their student loans" ranks 13 of 41 in priority for government action among US liberals, it ranks 38 of 41 among US conservatives.

The corresponding levels of disagreement for UK respondents are smaller. Looking at the same items, "Immigrants entering this country illegally" ranks 3 of 41 in priority for government action among the UK right, it ranks 20 of 41 among the UK left. Whereas "Young people being unable to pay
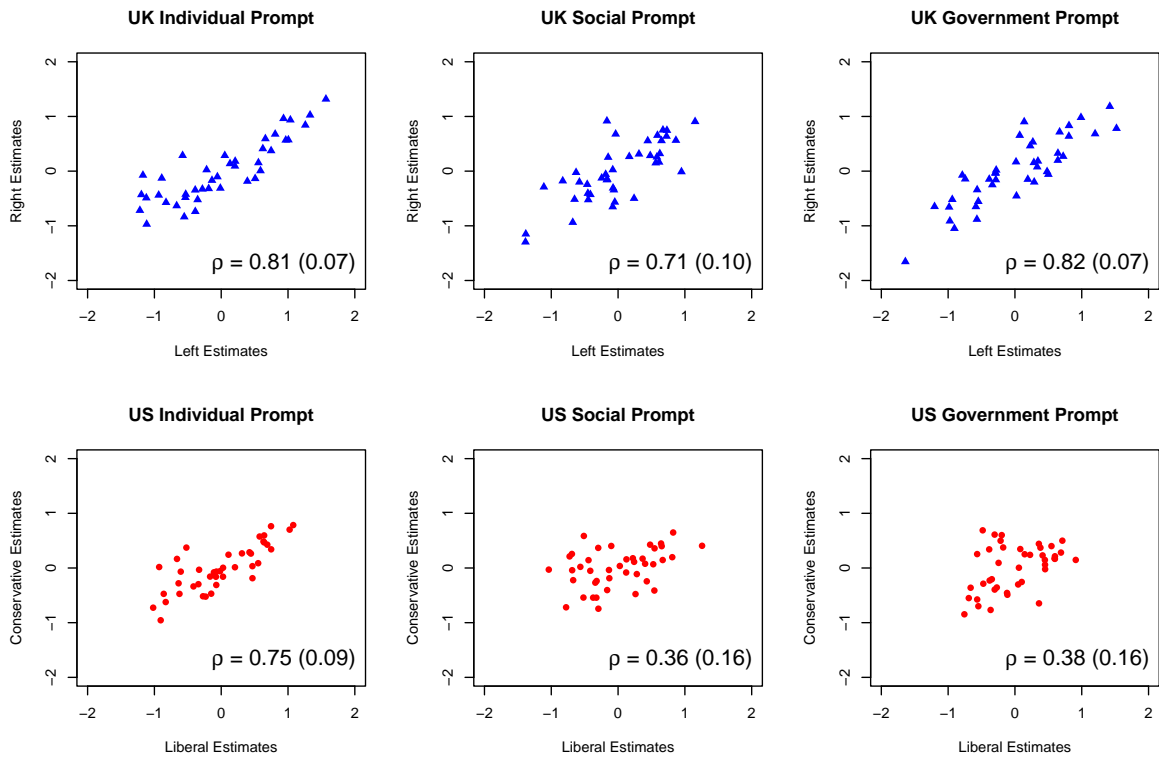

Figure 8: Comparison of Bradley-Terry estimates of different ideological groupings in the US and UK (rows), by prompt (columns).

off their student loans" ranks 22 of 41 in priority for government action among the UK left, it ranks 32 of 41 among the UK right. These are high salience, ideological issues in UK politics just as they are in the US, but there is not the same level of ideological divergence in public understanding of their relative priority.

Do differences in perceptions of prevalence predict the ideological patterns we find on the individual and social prompts? In appendix figure A7 we show there is somewhat greater agreement between left and right about the relative prevalence of different problems in the UK than there is between liberals and conservatives about the relative prevalence of different problems in the US. Ideological disagreements about the prevalence of problems predict how liberals and conservative respondents in the US answer the social prompt versus the individual prompt ($p = 0.006$), but this is not the case in the UK. Despite the relative imprecision of this analysis, we do see in the US data that on the issues where there is a larger difference between conservative and liberal perceptions of *prevalence,* the difference in conservative and liberal perceptions of problem *severity* increases more

between the individual and social prompts.

Discussion

We find that US and UK respondents make very similar evaluations of the relative severity of a set of 41 politically salient problems when considering them as individual events. There are disagreements within country as a function of ideology regarding the relative severity of these, but they are not large enough to yield very different orderings of which problems are more severe overall, and they appear on similar problems in both countries. When we move from considering individual instances of problems to their aggregate severity for society and their relative priority for government action, we see different patterns in the UK and US. In the UK, the ideological disagreements are similar in magnitude and on similar items to the individual prompt. In the US, the ideological disagreements grow in magnitude, amplifying disagreements about the individual instances of problems. As a consequence, while ideological disagreements about the relative magnitude of social problems are not large in the UK, US liberals and conservatives rank social problems and prioritise them for government action very differently.

One potential concern about our core findings is whether they could be the result the slightly different ideology questions we use in the US and UK. Could our results result from either the different wording or different public understanding of ideology in the two countries? We think the answer is no, for two reasons. First, we see exactly the same pattern as a function of past vote (appendix figure A5). Second, if there was an issue with the different meaning of ideology in the two countries, it is difficult to make a compelling argument that it should only manifest in the social and government prompts, but not in the individual prompt. Similarly, any concerns one might have about greater expressive responding in the US, that does not reflect individuals' real attitudes, would need to account for why this only occurs on some prompts and not others.

We have focused on ideology in our analysis both because we pre-registered this as our primary interest and also because it is the strongest predictor of variation in respondents' assessments of

problems. We present an additional analysis in the appendix using a hierarchical regression framework for modelling variation in respondents' assessments as a function of demographic variables plus self-reported ideology. This analysis shows that self-reported ideology is a far stronger predictor of variation in severity/priority assessments than age, education, and gender, in both countries and on all three prompts (appendix table A3), but there are some partial associations of the demographic variables in a model that includes ideology (appendix tables A4 - A9).

Another concern is whether our findings could be an artefact of the particular 41 problems that we chose to include. Our set of problems should be considered as a "convenience sample" drawn from the political news in both countries, looking at media with a range of ideological positions. Was there a different set of issues that we failed to include which would have been more divisive in the UK? One reason to think this is not very likely is again the fact that in the individual prompt the US and UK responses are very similar across problems and also with respect to ideological differences. A second reason to think this is not very likely is that we reviewed media in both countries and have, if anything, greater expertise on UK politics than US politics.

The fact that we have different results for the individual prompt versus the social and government prompts, in combination with our analysis of the direct prevalence and efficacy questions, suggests that the relevant mechanisms running through perceptions of problem prevalence are an important channel through which greater ideological differences arise in the US. However, we do not have individual-level data linking these, as we intentionally did not ask individuals about the same problems from their pairwise choices in the prevalence and efficacy questions, in order to avoid creating spurious associations due to the survey sequencing. Given that our core design aim was to cleanly measure views about relative problem severity and priority, we think that the approach taken was the best one, but it does leave mechanism questions to be assessed in future research.

One such question, which has already been interrogated in the existing literature on correcting political misperceptions, is the extent to which views about the relative severity of social problems can be changed through the supply of information about prevalence. For example, Hopkins, Sides and

Citrin (2019) show that providing accurate information about the size of the foreign-born population does little to affect attitudes towards immigration, even though these corrections do lead people to adjust their beliefs about the size of the foreign-born population. This kind of result highlights the challenge of studying mechanisms leading to different views across persons. The correlations between apparently logically related beliefs may arise independently from individuals' experiences or from communications and media consumption that are themselves correlated, rather than from maintained logical connections in the minds of the individuals. Nevertheless, while our data does not enable us to distinguish between internal versus external drivers of correlated beliefs about individual and social problem severity, and priority for government action, we hope that this framework is nevertheless useful for scholars who wish to understand how these attitudes might be related.

Conclusion

Political science research provides rich insight into voters' disagreements over what governments should do to deal with particular political problems. Far less attention has been paid to whether and how much voters disagree about which political problems should be prioritized for government action in the first place. In part, the lack of systematic study of problem prioritization reflects the difficulties of measuring variation in problem importance across groups using existing survey methods. It also reflects a lack of theoretical understanding of the determinants of voters' attitudes about the priority of different problems. In this paper, we attempted to address both barriers to understanding by describing some foundational theoretical insights about voters' priorities, and by introducing new methodological tools that allow us to measure theoretically important quantities relating to political polarization over problem importance.

We suggested at the outset of the paper that asking about the individual problem severity, social severity, and priority for government action is a way to interrogate the extent to which political disagreements reflect psychological differences between voters. Our individual, social and government prompts respectively correspond to respondents' psychological, sociological, and political evalua-

tions, with respect to a set of common objects. Our results suggest that the psychologies of UK and US citizens with respect to individual (bad) events/outcomes are not so different from one another, either cross-nationally or across the ideological spectrum. However US citizens hold substantially more ideologically divided sociological and political assessments than do UK citizens. We do see clearly that differences of individual psychology carry through across our prompts in the US as well as the UK. What is distinctive about the US is that they are amplified (see figure 7) in the transition from individual events to social perceptions in a way that they are not in the UK.

Why does this amplification of disagreement occur in the US? Both our theoretical model and empirical results suggest that one source of division stems from perceptions of the relative prevalence of different problems. This implies that we should be looking to the ways that the social and political information environment – such as distinctive features of the media (Broockman and Kalla, 2023) – differs between US and UK citizens. For instance, the role of Fox News has received extensive attention in the literature, most recently regarding evidence that exposure to Fox reduced compliance with anti-COVID measures (Ash et al., 2023; Simonov et al., 2020) because it reduced beliefs that COVID constituted a substantial problem. There is a broader conservative media ecosystem in the US that may not be matched in its reach by that in the UK, despite the fact that the UK does have substantial ideological differentiation in its media outlets. A media feedback loop in which individuals select into media exposure based on their prior orientation regarding what problems are more or less important, and then are differentially exposed to news which emphasizes the prevalence of those problems over others, is a plausible mechanism for amplifying differences in individual morality into larger disagreements about social problems and priorities for government action.

Our study is also a contribution to improving an area of survey measurement that has long frustrated academic and non-academic analysts. The "most important problem" question form is pervasive in academic surveys, but the measurement properties of this instrument have been widely questioned (Bartle and Laycock, 2012; Johns, 2010; Wlezien, 2005; Jennings and Wlezien, 2011; Dennison, 2019). We think that pairwise comparison experiments are a far better way to get at which problems

people tend to think are more important. Compared to open-ended response questions, the pairwise comparison approach facilitates data collection on a wide set of concrete problems rather than generating responses relevant to only a small set of broad issue areas. Compared to single-item rating questions, paired comparisons require only that respondents are able to make judgments about the relative priority of problems, rather than placing individual problems on arbitrary scales in a consistent way.

Particularly in cases where researchers are interested in aggregate rankings of the importance of a large number of specific political problems, the design we develop here could be profitably applied in a wide variety of surveys and could be used to track change in public priorities over time. Having defined a set of problems to track, it would be possible to use supervised measurement techniques applied to corpora of political speech and to media publications to track which of that defined set of problems are receiving most attention. Tracking changes in public priorities over time using a comparable methodology would enable new research on issue salience in politics by examining the dynamics of, and between, public priorities, politician attention, and media attention.

In this paper, we demonstrated the use of our measure of problem importance as a dependent variable, and showed how to use a multilevel model to explain variation in perceptions of problem importance as a function of country, prompt type, and ideology. One disadvantage of the paired-comparison design is that it does not easily provide measures of problem prioritisation at the individual-level, which makes it harder for our measures to be used as independent variables.[8] However, even without the pairwise-comparison set-up, we think our results are nevertheless relevant to survey researchers who are interested in individual variation in measures of issue importance. Most prominently, many voting models view issue-salience as an important moderator of distance-based vote choice, but these individual measures are largely based on questions which elide the important distinctions between problem severity, social severity, and need for government action that our findings

---

[8]This problem is analogous to issues faced by other survey designs – such as conjoint and list experiments – in which it is straightforward to estimate the average or subgroup treatment effects, but where estimating individual-level effects requires very burdensome data collection (e.g. Zhirkov, 2022).

reveal. Future research may therefore benefit from applying our core theoretical ideas – in which we decompose issue "importance" into distinct concepts which vary empirically – to other forms of survey question that more easily facilitate measurement at the individual level.

Taken together, we believe that elements of the design we develop here could be profitably applied in a wide variety of surveys and could be used to track change in public priorities over time. We present a two country comparative study, which already reveals interesting and important cross-national differences. A larger scale version of this study would enable us to understand the extent to which citizens in different social and political contexts share common views about the problems that they might encounter in their lives, that their societies face, and that their governments might aim to do something to fix.

Statement on Research Ethics

The research ethics committee for the our home institution, [redacted for peer review], determined that the survey experiment described in the paper was exempt from full ethics review because the survey involved "the use of [a] non-sensitive, completely anonymous survey" and "it is not possible to identify individuals from the information provided". We also note that our survey required no deception.

Differences between Prompts by Problem

Figure A1: Difference between Bradley-Terry Estimates for severity of social problems and corresponding individual problems, in the UK (blue) and US (red). .
Figure A2: Difference between Bradley-Terry Estimates for priority for government action and corresponding severity of social problems, in the UK (blue) and US (red).
Figure A3: Difference in Bradley-Terry Estimates between right/conservatives and left/liberals, for social prompt, in the UK (blue) and US (red).

Figure A4: Difference in Bradley-Terry Estimates between right/conservatives and left/liberals, for government prompt, in the UK (blue) and US (red).

Bradley-Terry Estimates by Past Vote
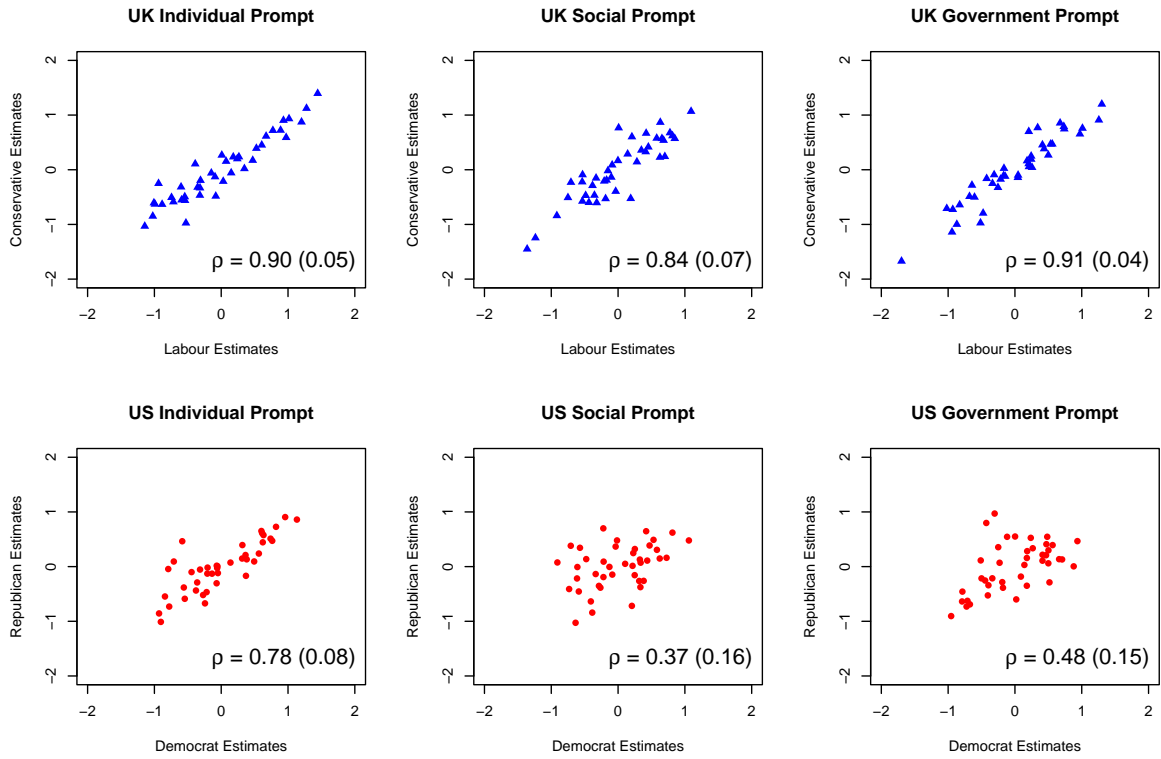

Figure A5: Comparison of Bradley-Terry estimates of different past vote groupings in the US and UK (rows), by prompt (columns).

Figure A6: Correlations between Bradley-Terry estimates for all country (UK, US) by ideology (Left, Moderate, Right) by prompt (Individual, Social, Government) groups. Comparisons varying more than one of these three omitted to aid visualisation.

Table A1: Treatment texts

Individual	Social
A child goes hungry because their parents can't afford enough food.	Children going hungry because their parents cannot afford enough food.
A young person is killed by a gang.	Young people being killed by gangs.
A mass shooting with many deaths.	Mass shootings with many deaths.
A parent abandons their family.	Parents abandoning their families.
A person dies in a car accident.	People dying in car accidents.
A person dies from a shark attack.	People dying from shark attacks.
A person is bankrupted by medical expenses.	People being bankrupted by medical expenses.
An animal is mistreated by its owner	Animals being mistreated by their owners
A person abuses their spouse or partner.	People abusing their spouses or partners.
Rising energy prices force a business to close.	Rising energy prices forcing businesses to close.
High interest rates make it impossible for someone to buy a home.	High interest rates making it impossible for people to buy homes.
A person is scammed out of their life savings.	People being scammed out of their life savings.
Rising prices reduce a person's standard of living.	Rising prices reducing peoples' standards of living.
A young person is unable to pay off their student loans.	Young people being unable to pay off their student loans.
A person is fired from their job to maximize company profits.	People being fired from their jobs to maximize company profits.
A wealthy person moves their wealth abroad to avoid paying tax in this country.	Wealthy people moving their wealth abroad to avoid paying tax in this country.
A business person commits fraud to enrich themselves.	Business people committing fraud to enrich themselves.
A person dumps their [rubbish/trash] in a residential area.	People dumping their [rubbish/trash] in residential places.
The police stop and search a person without reasonable suspicion of criminal activity.	The police stopping and searching people without reasonable suspicion of criminal activity.
A person claims [benefits/welfare benefits] that they are not entitled to claim.	People claiming [benefits/welfare benefits] that they are not entitled to claim.

A person is prevented from wearing something that is important to their religion.	People being prevented from wearing things that are important to their religion.

Right-Left Differences by Prompt by Moral Foundations Theory Category

Before conducting our experiment, we pre-registered a coding of our 41 problems into six Moral Foundations Theory (MFT) categories (Care, Fairness, Sanctity, Loyalty, Authority, Liberty). Of the 41 problems, 36 were coded into a single MFT category, and the remainder were coded as equally in two categories. In regression table A2, we regress the difference in Bradley-Terry estimate between right/conservatives and left/liberals, by prompt and by country, on these MFT category weights. This yields an estimate of an average ideological difference by problem type. Problems coded as relating to care and fairness tend to be rated as more severe / higher priority by left/liberals (negative right-left differences); problems relating to sanctity, loyalty, authority and liberty tend to be rated more highly by right/conservatives. The patterns are largely similar across both countries, however there is a suggestion that sanctity-coded problems have a much larger ideological difference in the US than the UK across the prompts.

Table A2: Linear regressions of the problem-level differences in Bradley-Terry estimate between those self-identifying right/conservative and left/liberal, by country and prompt.

Individual Responses and Population Average Parameters

Individual question responses to a pairwise comparison prompt can be expected to depend on an individual's d_{ij}, s_{ij}, or g_{ij}. We can write these in terms of the relevant group means as $d_{ij} = d_j + v_{ij}^d$ where v_{ij}^d have mean zero (and equivalently for s and g). Thus, in the case of the individual prompt, we have:

$$Y_i^* = \left(d_{j(i)} + v_{ij(i)}^d \right) - \left(d_{j'(i)} + v_{ij'(i)}^d \right) + \epsilon_i$$

The two v and the ϵ are all mean zero, so their sum is also mean zero. Conventionally $\epsilon \sim N(0, 1)$ in an ordered probit model to identify the latent scale. If we assume that the v are also normally distributed, all three of these error terms collapse into a single, mean zero, normally distributed error term. The variance of this error term can be set to 1 without loss of generality, so long as the variance of individual assessments of problem severity and priority around their population means are equal across problems. Thus the Bradley-Terry model estimates the population means of d_{ij}, s_{ij}, or g_{ij}, so long as this homoscedasticity assumption is met.

Demographic Predictors of Variation in Pairwise Comparison Responses

Our main analysis uses a correlated severity model to estimate the Bradley-Terry parameters that best fit disjoint sub-groups of our sample. Here, in order to confirm that self-reported ideology is the strongest predictor variation in respondents' relative assessments, we describe a *covariate severity model* which similarly starts with the first-stage model described in equation 6. We then hierarchically model the α parameters by assuming that they follow a linear function of predictor variables $X_{i,k}$ measured for each respondent i. Where $\beta_{k,p}$ is the coefficient for problem p on variable k, we assume:

$$\alpha_{j,p,i} \quad = \quad \sum_{k=1}^{K} \beta_{k,p} \cdot X_{i,k} \tag{A1}$$

$$\beta_{k,p} \quad \sim \quad N\left(0, \sigma_{\beta,k}\right) \tag{A2}$$

We define $X_{i,1} = 1$, so that each $\beta_{1,p}$ is the "intercept" for the severity for problem p, which is the baseline severity estimated for individuals with all X variables equalling zero. Then, the set of additional β parameters for a given problem p describe how respondents' relative severity for that problem varies around that intercept as a linear function of the included X variables. The model is set up using regularisation on the coefficients that is governed by a explanatory variable k specific variance $\sigma_{\beta,k}$, which identifies the general scale for the pairwise comparison experiment overall and avoids overfitting to small numbers of comparisons for specific problems and respondent demographic variable combinations. This approach also provides information about which variables k tend to have larger coefficients across the set of problems p that we studied, as these will have larger estimated $\sigma_{\beta,k}$ than variables that (conditionally) predict less variation. Thus, these "variance of predictive power" parameters $\sigma_{\beta,k}$ are our primary quantities of interest for answering the question of which respondent-level variables most strongly predict variation in responses to the pairwise comparison questions. To make these meaningfully comparable relative to the demographic variation in the sample, we standardise all X variables $k \in 2, \ldots, K$ in these model. We can also examine the values of specific elements of β for particular problems p as a function of particular respondent variables k, to learn something about which respondents view which problems as more/less severe, other variables constant, in each country and on each prompt. We present a table of the σ_β parameters for all variables in all country-prompts (Table A3), and then six tables of the β parameters, one for each country-prompt (Tables A4 - A9.

Table A3 reveals a consistent pattern that, across both countries and all six prompts, ideology is the strongest predictor (largest σ_β) of variation in problem assessments in a model that also includes age, gender and whether someone received a university degree (3 year UK, 4 year US). The estimates of the individual β parameters in tables A4 - A9 show this collectively, but also reveal specific issues where particular demographic variables are predictive. For example, in table A9, we see that in the US, in the government action prompt, looking at the age variable, we see that (holding constant self-reported ideology, gender and education) older people are more concerned about rising energy prices and illegal immigration, younger people are more concerned about people being fired from their jobs, police searches, and shark attacks. These are all fairly easy to understand demographic associations, given the incidence of these problems and other known attitudinal patterns. Similarly, the only two significant gender effects in that table are that women are more concerned about teenagers regularly watching pornography than men and less concerned about teenagers gender transitioning using medication.
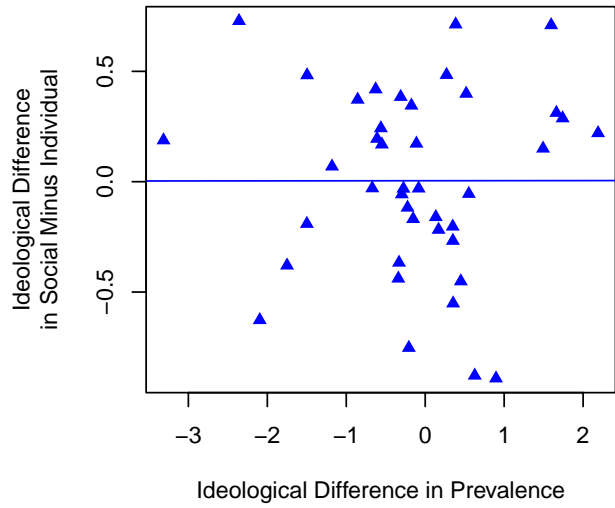

Figure A7: Relationships between mean prevalence responses for each problem from left/liberal and right/-conservative respondents (left column). Relationship between change in ideological relationship between individual and social prompt and ideological differences in perceived prevalence (right column).
